# This paper was written under the aegis of the SPF Financial and Monetary Policy Reform Project at the National Institute for Public Finance and Policy, New Delhi. We are grateful to the editor, Ping Chen, and two referees for insightful comments. We especially thank Abhijit Banerjee, Rudrani Bhattacharya, and Bo Yang for comments, as well as participants at the `Business Cycle Facts and DSGE Model for India' 2010 workshop at NIPFP, Workshop 5 of the Center for International Macroeconomic Studies (Surrey University), the 7th Australian Development Workshop (Perth), the 2011 KAS-ICRIER financial sector seminar, and the 12th Neemrana-NBER conference for useful insights.
Abstract

This paper presents a comprehensive set of stylised facts for business cycles in India from 1950-2010. We show that most macroeconomic variables are less volatile in the post reform period, even though the volatility of macroeconomic variables is still high and similar to other emerging market economies. Consistent with other emerging market economies, consumption volatility has gone up, a result that is robust to a variety of specifications. In terms of co-movement and persistence however, India looks more similar to advanced economies, and less like other emerging market economies. We argue that these changes are driven primarily by structural changes caused by liberalization policy, and not by “good luck.”.

1 Introduction

This paper describes the changing nature of the Indian business cycle from 1950 - 2010. Our focus is to compare India’s business cycle in the pre 1991 economy, with the post 1991 Indian economy, after the large scale liberalization reforms of 1991. We show that after 1991, key macroeconomic variables are less volatile in the post reform period compared to the pre-reform period. However, the volatility of macroeconomic variables in the post-reform period in India is still high and similar to emerging market economies. Consistent with other emerging market economies, we also find that consumption volatility has gone up in the post reform period. We show that this result is robust to a variety of specifications. In contrast, in terms of co-movement and persistence, the Indian business cycle looks more similar to advanced economies, and less like emerging market economies in the post reform period.

While our paper is the first exercise to comprehensively document - using both annual and quarterly data - an exhaustive set of stylized facts for the Indian business cycle in the pre and post reform period, we use the data to report evidence that these changes are driven primarily by structural changes caused by liberalization policy, and not by “good luck.” Thus, increases in globalization, sectoral shifts, and milder differences between growth rates in growth slowdowns and expansions has led to a better ability to absorb shocks.

In recent years, considerable research in the field of international business cycle has focused on documenting stylized features of business cycles and developing dynamic stochastic general equilibrium models - both of the RBC and New Keynesian type - to explain them. Traditionally, studies in this area of research have primarily dealt with documenting business cycle features of major developed economies (Kydland and Prescott, 1990; Backus and Kehoe, 1992; Stock and Watson, 1999; King and Rebelo, 1999). There has also been a growing interest in understanding the business cycle features of developing and emerging market economies (Agenor et al., 2000; Rand and Tarp, 2002; Male, 2010) and comparing them with those of developed

\[1\] In terms of the Indian convention, this means 1950-51 to 2009-2010. Both annual and quarterly data are in 2004-2005 base year prices. The quarterly data goes from the second quarter (Q2) of 1999, to Q2 2010.

\[2\] It is well known that because the reform process in India proceeded in a slow manner, with major reforms - such as the removal of quantitative restrictions on imports - not put into place in 2001, the effective post reform starting year should be 2001. Since our quarterly dataset starts from the second quarter of 1999, we don’t report the post 2001 Indian business cycle properties separately.
economies (Neumeyer and Perri, 2005; Aguiar and Gopinath, 2007). (Kim et al., 2003), for instance, examines the nature of business cycles in emerging Asian economies.

India provides an interesting example as the nature of cycles have changed after India liberalised its economy. In 1991 India moved away from a planned, closed economy characterised by controls on capacity creation and high import duties to a market determined industrializing open economy. In terms of policy, in the pre 1991 Indian economy, monetary policy played an accommodative role to fiscal policy. The financial sector’s primary function was to lend support to the government’s funding needs. Since the mid 1990s, financial repression has steadily declined. Trade liberalization has also been substantial since 1991.\textsuperscript{3} Our claim is that liberalization policy led to structural changes which changed the properties of the Indian business cycle. Our paper extends the existing literature by investigating the change in the nature of Indian business cycle in response to structural changes induced by changes in the policy environment.

We compare the properties of Indian business cycle over two periods: 1950-1991 for the pre-liberalisation period and 1992-2010 for the post-liberalisation period. GDP, private consumption, total gross fixed capital formation, consumer prices, exports, imports, government expenditure, M1, M3, reserve Money, inflation, and the nominal exchange rate, are the key variables analysed. The emerging business cycle literature reports strong counter-cyclicality of net exports and highly volatile and counter cyclical interest rates in emerging markets. We also report the business cycle properties of these variables for India, though our results differ. We adopt the commonly used Hodrick-Prescott filter to derive the cyclical components and then check the robustness of our results with the Baxter-King filter, quarterly data, and different sub-samples. The cyclical components are then used to study the business cycle characteristics relating to volatility, co-movement and persistence.\textsuperscript{4}

Our main finding is that after the liberalisation of the Indian economy in 1991, the properties of the Indian business cycle resemble an economy closer in some ways to advanced economies. Specifically, we find that key macroeconomic variables in our dataset are less volatile in the post reform period compared to the pre-reform period. The reduction in volatility resembles that of advanced economies (Kydland and Prescott, 1990; Backus and Ke-

\textsuperscript{3}See (Gangopadhyay and Shanthi, 2012) and (Ghate and Wright, 2012).

\textsuperscript{4}We follow the standard procedure in the international business cycle literature and decompose the time series into secular and cyclical components. Several methods are available for implementing this type of trend-cycle decomposition.
hoe, 1992; Stock and Watson, 1999; King and Rebelo, 1999) and other Asian economies (see Kim et al. (2003)) that have experienced structural transformation. We argue that these changes are driven primarily by structural changes caused by liberalization policy, and not by ”good luck”.

However, we find that the level of volatility of macroeconomic variables in the post-reform period is still high and comparable to emerging market economies. In terms of emerging markets, this is consistent with the findings of Male (2010) Neumeyer and Perri (2005) Alper (2002) that report higher output volatility for developing and emerging market economies. In addition, consumption is more volatile than output in the post-reform period. This is similar to the findings of Kim et al. (2003) who report higher relative consumption volatility for most of the Asian economies in the second period. To the extent that increasing international financial integration allows countries to better smooth consumption through international risk sharing, an increase in consumption volatility is a puzzle. However, our findings are consistent with the large literature on the apparent disconnect between the theoretical predictions of the financial liberalization process, and country specific findings.

In contrast, in terms of co-movement and persistence, the Indian business cycle looks similar to advanced economies. There is an increase in the co-movement of investment with respect to output. Imports have become more pro-cyclical in the post reform period. Net exports show a transition from being a-cyclical in the pre-reform period to counter-cyclical in the post reform period. There is also higher persistence for all the key macroeconomic variables in the post reform period. India thus looks more similar to advanced economies, and less like emerging market economies, when we look at the co-movement and persistence of key macroeconomic variables. A key feature that distinguishes emerging economies from developed economies is the pro-cyclicality of monetary policy. Consistent with this literature, we report evidence of pro-cyclical monetary policy in the post-reform period using a variety of indicators.

The remainder of the paper is structured as follows. Section 2 outlines the main features of emerging economies business cycle with an overview of the

\[\text{Ang (2011) finds that financial liberalization magnifies consumption growth volatility in India. Kose et al. (2009) find no evidence of international risk sharing in an emerging market sub-sample that includes India. See also Broner and Ventura (2010).}\]

\[\text{A comprehensive literature has focused on the pro-cyclicality of monetary policy in emerging market economies. The underlying rationale for the pro-cyclicality of monetary policy stems from the inconsistencies arising from the impossible trinity. See Frankel, Patnaik and Shah (2010).}\]
sources of shocks in these economies. Section 3 outlines the data sources and the variables included in the study. Section 4 provides empirical evidence on the changing Indian business cycle stylised facts from pre to post reform period. Section 4.2 presents a snapshot of India’s transition. Section 5 presents results on sensitivity tests. Section 6 concludes. Appendix A lists the sources and definitions of variables used in this study. Appendix B details the methodology employed to compute the Indian business cycle stylised facts. Appendix C details the procedure through which TFP has been calculated.

2 Business Cycles in Emerging Market Economies

One of the main features that distinguishes emerging economies business cycles from advanced economies is their higher volatility. Current account balances, output growth, interest rates, and exchange rate tend to exhibit larger, and more frequent changes (Calderón and Fuentes, 2006). In particular, consumption in emerging market economies is typically more volatile than output; real interest rates are highly volatile and counter-cyclical, and net exports are strongly counter-cyclical. We reproduce Table 1 from the seminal work on emerging market business cycles by Aguiar and Gopinath (2007) to locate the position of Indian business cycle vis-a-vis other developed and developing economies. The analysis in Aguiar and Gopinath (2007) covers 13 developed and 13 emerging economies based on a quarterly dataset.

---

7 We refer to this paper as it provides average figures for business cycle characteristics for developed and developing economies.

8 Australia, Austria, Belgium, Canada, Denmark, Finland, Netherlands, New Zealand, Norway, Portugal, Spain, Sweden and Switzerland comprise the sample of developed economies while Argentina, Brazil, Ecuador, Israel, Korea, Malaysia, Mexico, Peru, Philippines, Slovak Republic, South Africa, Thailand and Turkey comprise the set of emerging economies.

Table 1 shows that the business cycle characteristics of developed and emerging economies differ on some important dimensions. Emerging economies, on an average have higher output volatility compared with the developed economies: Table 1 shows an average volatility of 1.34 for developed economies and 2.74 for emerging economies. Consumption also tends to be more volatile than output in emerging economies: the average relative volatility of consumption is 1.45 for emerging economies and 0.94 for developed economies. Relative investment volatility is comparatively higher for emerging economies at 3.91, compared to 3.41 for developed economies. Thus, the findings in Table 1 are broadly consistent with the findings of other papers on the business cycle stylised facts of developing economies.

To study these features, the small open economy RBC model has been widely used (Aguiar and Gopinath, 2007; Neumeyer and Perri, 2005; Uribe and Yue, 2006; Garcia-Cicco et al., 2010). Aguiar and Gopinath (2007) for instance allow for permanent and transitory changes to productivity. In their view, emerging markets are characterized by a large number of regime shifts, which are modeled as changes in trend productivity growth. A shock to the growth rate implies a boost to current output, but an even larger boost to future output. Consumption responds more than income, reducing savings and generating a current account deficit. If growth shocks dominate transitory income shocks, the economy resembles a typical emerging market with its volatile consumption process and counter-cyclical current account. By contrast, developed economies typically face stable economic and political regime changes. Hence, a developed economy characterised by relatively stable growth process will be dominated by standard, transitory productivity shocks. Such a shock will generate an incentive to save that will offset any increase in investment, resulting in limited cyclical of the current account.

9 The paper does not report the absolute standard deviation of variables.
10 However, counter-cyclical net exports is also reported for developed economies by
The small open economy RBC model approach to studying emerging market business cycles is not without criticism. For instance, Calderón and Fuentes (2006) suggest that because the sources of shocks in Aguiar and Gopinath (2007) remain a black box, it is not clear whether these are being driven by changes in economic reforms, or other market frictions. Indeed, Chari et al. (2007) show that a variety of frictions can be represented in reduced form as Solow residuals. Garcia-Cicco et al. (2010) show that when estimated over a long sample, the Aguiar and Gopinath (2007) RBC model driven by permanent and transitory shocks does a poor job in explaining observed business cycles in Argentina and Mexico, along a number of dimensions. These findings of Garcia-Cicco et al. (2010) suggest that the RBC model driven by productivity shocks may not provide an adequate explanation of business cycles in emerging economies.

Other papers in the literature, such as Neumeyer and Perri (2005) emphasize the interaction between foreign interest rate shocks and domestic financial frictions that drive business cycle fluctuations in emerging market economies. Firms in their model demand working capital to finance their wage bill making labour demand sensitive to interest rate fluctuations. An increase in the emerging market country’s interest rate leads to a rise in labour costs. Since labour supply is insensitive to interest rate shocks, a lower demand for labour leads to lower levels of employment and output in equilibrium. Uribe and Yue (2006) find that both country interest rates drive output fluctuations in emerging market economies as well as the other way around. Kose et al. (2003) analyse the importance of domestic and external factors as causing cycles. Calvo (1998) argues that the idea of sudden stops are an important determinant of large cycles in emerging markets.

2.1 Relevance of the RBC approach to India

Two issue arise in the modeling of Indian business cycles using the small open economy RBC approach. The first is the relevance of the small open economy assumption. This is because many emerging market economies, such as India, are highly regulated with limited foreign direct investment (FDI). Consequently, the appropriate comparison for India would be other large developing or large emerging market economies.

To address this, we plot two figures in Figure 1. The first graph of Figure 1 is
plots the FDI to nominal GDP ratio for select emerging market economies.\textsuperscript{11} The graph shows that before the onset of the global financial crisis of 2008, India’s FDI as a percentage of GDP is amongst the largest.\textsuperscript{12} Further, in 1992, during the first year of the post reform period in India, FDI as a percentage of nominal GDP was in a similar range to other emerging market economies such as Brazil and South Africa.\textsuperscript{13}

**Figure 1** Measures of openness

The second graph of Figure 1 plots the Lane and Milesi-Ferretti (Lane and Milesi-Ferretti, 2007) measure of financial openness, which is a widely used measure of \textit{de facto} financial integration. The Lane and Milesi-Ferretti measure measures the stock of all external assets and liabilities of a country expressed as a ratio of GDP. As the graph shows that for select economies, India’s value in this measure lies in a similar range to other small open economies like Turkey and Brazil.

Finally, while we do not report these results here, we have also compared India’s business cycle properties with another large and similarly sized emerging economy: Brazil.\textsuperscript{14} We find that the main properties of business cycles in

\textsuperscript{11}The countries are South Africa, Brazil, China, Russia, Turkey, and Korea.

\textsuperscript{12}The data have been obtained from UNCTAD [http://unctadstat.unctad.org/Tableviewer/tableView.aspx]

\textsuperscript{13}In 2010, India’s share of total exports was 1.5 %; its share of total imports was 2.12 %. These miniscule shares further validate the small open economy assumption. See Table 1.6 and Table 1.7 in [http://www.wto.org/english/res_e/statis_e/its2011_e/its11_world_trade_dev_e.htm] It should also be noted that in the DSGE literature, treating India as a small open economy is not without precedent. See [Batini et al., 2010].

\textsuperscript{14}These are available from the authors on request. We do not report stylized facts for China because of the lack of availability of quarterly macroeconomic data for a comparable time period.
Brazil are similar to the stylized facts India and for the (small open) emerging economy averages reported in Table 1.

The second issue concerns the relevance of the equilibrium approach to understanding business cycles in a developing economy such as India, and in particular, its usefulness in studying India’s experience in the Asian financial crisis of 1997, and the Great Recession of 2008. Our view is that the small open economy RBC model appears as a reasonable first approximation to thinking about business cycles in India. Future work can use the findings of this paper to assess the extent to which DSGE models, starting with the simplest RBC model through to New-Keynesian models with labour markets and financial frictions introduced in stages, can explain business cycle fluctuations in India. Both closed and open economy models can be examined. Comparisons with a representative developed economy, say the US, can then be made. Proceeding in this way, one will be able to assess the relative importance of various frictions in driving aggregate fluctuations in India.

3 The Dataset

The business cycles examined in the literature are typically known as growth cycles, extending from the work of Lucas (1977) where the business cycle...
component of a variable is defined as its deviation from trend\textsuperscript{17}

We follow this standard methodology in deriving the stylised facts for Indian business cycles. In Appendix\textsuperscript{3} we detail the statistical procedure used to extract the business cycle. In India, quarterly data for output and key macroeconomic variables is available only from June 1999. To understand the changing nature of Indian business cycles, we examine annual data. We then check the validity of our results with quarterly data. This is consistent with the literature on stylised facts (King and Rebelo\textsuperscript{1999}; Stock and Watson\textsuperscript{1999}; Male\textsuperscript{2010}), that relies on quarterly data to study business cycle properties of macroeconomic variables. Following King and Rebelo\textsuperscript{1999} we choose private consumption and investment as key variables. In addition, we analyze exports, imports, net exports, consumer prices (Consumer Price Index-Industrial Worker \((\text{cpi-iw})\))\textsuperscript{18}, government expenditure and a range of nominal variables such as the nominal exchange rate and different measures of the money supply. Data on hours worked is not available for India. We use GDP as a measure of aggregate activity in the economy.

For the annual analysis, we have a sample period covering 1950-2010. To study the transition of the economy, the data is analyzed in two periods: the pre-liberalisation period from 1950-1991 and the post liberalisation period from 1992 to 2009. The primary data source is the National Accounts Statistics of the Ministry of Statistics and Programme Implementation. The data for consumer prices is taken from the Labour Bureau, Ministry of Labour and Employment. The data for government expenditure is taken from the budget documents of the Government of India. GDP, private consumption, gross fixed capital formation, exports and imports are expressed at constant prices with base 2004.\textsuperscript{19} Government expenditure is expressed in real terms by deflating it with the GDP deflator. Following Agenor \textit{et al.}\textsuperscript{2000} and

\textsuperscript{17}Business cycles dating goes back to the early work by (Burns and Mitchell\textsuperscript{1996}). The classical approach propounded by (Burns and Mitchell\textsuperscript{1996}) defines business cycles as sequences of expansions and contractions in the levels of either total output or employment. In 1990, (Kydland and Prescott\textsuperscript{1990}) established the first set of stylised facts for business cycles in other developed economies, based on their research of US business cycle.

\textsuperscript{18}In most countries the headline inflation number is consumer prices, in India it is wholesale prices. We follow the literature on stylized facts in using consumer prices.

\textsuperscript{19}For their analysis of investment, King and Rebelo\textsuperscript{1999} use only the fixed investment component of gross domestic private investment. The other components of gross domestic private investment are residential and non-residential investment. The volatility of gross domestic private investment in the US is higher than the component of fixed investment as residential investment is highly volatile. We take gross fixed capital formation as a proxy for investment since unlike the US, we do not have data on the categories of gross investment.
Neumeyer and Perri (2005) net exports is divided by real GDP to control for scale effects. We source the data from the Business Beacon database produced by the Centre for Monitoring Indian Economy (CMIE), who source it from the primary data sources mentioned above. All variables and their sources are described in detail in the Appendix.

The variables analyzed are first log transformed. The cyclical components of these variables are then obtained from the Hodrick-Prescott filter, as is standard in the literature (King and Rebelo, 1999; Agenor et al., 2000; Neumeyer and Perri, 2005). The cyclical components are then used to derive the business cycle properties of the variables in terms of their volatility, co-movement and persistence. For the sensitivity analysis, we test the robustness of our results by using the band-pass filter of Baxter-King (Agenor et al., 2000).

As a further check, we also use quarterly data to verify the validity of our results.

4 The Indian Business Cycle

Table 2, which constitutes the main finding of this paper shows the changing nature of the Indian business cycle from 1950 - 2010.

The main features can be summarized as follows:

- **Increased consumption volatility**: A robust finding of our paper is the increase in consumption volatility in the post reform period. In particular, private consumption has seen a marginal increase in volatility from 1.82 to 1.87 in the post-reform period. This is similar to the experience of other emerging economies, and in particular, other emerging Asian economies. This result is robust to use of the Baxter-King filter (Section 5.3), use of quarterly data (Section 5.2), and across different sub-samples (Section 5.4).

- **Volatility of key macroeconomic variables has fallen**: High macroeconomic volatility is considered both a source as well as reflection of underdevelopment (Loayza et al., 2007). Aggregate GDP has seen a decline in volatility from 2.13 in the pre-reform period to 1.78 in the 2000s. Much of the literature following Nelson and Plosser (1982), supports the view that it is impossible to distinguish large stationary auto-regressive roots from unit auto-regressive roots, and that there might be non-linear trends. With a near unit root, linear de-trending will lead to spurious cycles. See Stock and Watson (1999).

</table>

post-reform period. This is consistent, in particular, with the experience of other major Asian economies (Kim et al., 2003). This is due to a decline in volatility in the agricultural component of GDP. The volatility of non-agriculture GDP however has gone up in the post-reform period. The volatility of investment has declined from 5.26 in the pre-reform period to 5.10 in the post-reform period. Consumer prices, imports, government expenditure and nominal exchange rate have also become less volatile in the post-reform period. Inflation has also become less volatile - akin to the Great Moderation experienced in the US. While government expenditures are less volatile in the post reform period, they are still more volatile than output. However, the fall in volatility is not common to all the macroeconomic variables that we consider. For instance, exports has seen a marginal increase in volatility from 7.14 to 7.71 respectively in the post-reform period.

- **Increased pro-cyclicality of investment with output**: A significant feature of modern capitalist economies is that investment is highly procyclical vis-a-vis the aggregate business cycle. Table 2 reports a significant increase in contemporaneous correlation of investment with output.

---

21 The volatility of the agricultural GDP has fallen to half from 4.26 in the pre-reform period to 2.56 in the post-reform period due to better agricultural performance.

22 In advanced economies, it is less volatile than output.
from 0.22 in the pre-reform period to 0.60 in the post reform period.

- **Increased pro-cyclicality of imports with output**: Imports have become pro-cyclical in the post-reform period. The external sector policies in the pre-reform period were based on protectionism and import licensing. This is reflected in a negative correlation of imports with output in the pre-reform period. The policy thinking underwent a major change in post 1991 period. Tariff barriers were reduced and non-tariff barriers were dismantled in the mid 1990s. The demand for raw material imports increased substantially with easing of capacity controls on industries. This resulted in imports fluctuating with changes in aggregate business activity. Table 2 shows an increase in the contemporaneous correlation of imports from an insignificant -0.19 in pre-reform period to 0.70 in post reform period. The pro-cyclical nature of imports is again a feature similar to those for advanced open economies.

- **Counter-cyclical nature of net exports**: Since imports are significantly pro-cyclical and exports are not highly correlated with GDP, on balance this leaves us with a counter-cyclical nature of net exports. Table 2 shows a transition from a-cyclical relation in net exports to counter-cyclical net exports.

- **Counter-cyclicality of nominal exchange rate**: The nominal exchange rate has turned counter-cyclical in the post-reform period. From an a-cyclical relation in the pre-reform period, the post-reform period shows that the exchange rate goes up in bad times and moves down in good times. This is indicative of the presence of a flexible exchange rate regime in the post-91 period.

- **Pro-cyclicality of monetary policy**: A key feature that distinguishes emerging market economies from developed economies is the pro-cyclicality of monetary policy. Table 2 shows a clear pro-cyclical monetary policy in the post-reform period. Pro-cyclical capital flows with a "managed" exchange rate has induced a pro-cyclical monetary policy response in the post reform period.

- **Persistence** As mentioned before, persistence indicates the inertia in business cycles. It also captures the length of observed fluctuations. Real GDP exhibits weak persistence in the pre-reform period, although there is higher persistence in pre-reform non-agricultural GDP. In the post-reform period, the persistence of real GDP increases substantially, which provides more leeway for predicting the course of business cycles. In general, all variables reveal low persistence in the pre-reform period,
with higher persistence in the post-reform period.

4.1 Comparison with other economies experiencing structural change

A careful look at Table 2 shows that though the level of volatility of key macroeconomic variables has declined, it is still high and similar to emerging market economies. For example, the volatility of real GDP declines from 2.13 to 1.78 in the pre to post reform period. These numbers are closer to the volatility statistics reported by Kim et al. (2003) for Asian economies before and after the structural transformation respectively. The volatility numbers are also comparable to those reported by Alper (2002) for Mexico and Turkey but much higher than the numbers reported for the U.S. An interesting finding is that the relative volatility of consumption has gone up in the post-reform period, again similar to the findings reported by Kim et al. (2003). While the absolute volatility of trade variables has marginally declined, the relative volatility is still high. This is consistent with the findings of Kim et al. (2003) who report reduced but still higher relative volatility of trade variables as compared to those of the G-7 countries.

In contrast, the Indian business cycle is similar to the developed economies on co-movement and persistence of macroeconomic variables. Table 2 shows that the contemporaneous correlation of investment with output increases from 0.22 in the pre-reform period to 0.77 in the post-reform period. While the post-reform correlation figure is higher than the number reported by Kim et al. (2003) for Asian economies for their second period, it is similar to the numbers reported by Male (2010) for developed economies. Similarly, the correlation of imports with output increases in the post-reform period. The figure reported in Table 2 is much higher than the corresponding average correlation figures reported by Kim et al. (2003). Another feature on which the Indian business cycle resembles that of an advanced economy is the persistence of macroeconomic variables. As an example, the persistence of output reported in Table 2 is greater than the average persistence figures reported for Asian economies by Kim et al. (2003) and for developing economies by Male (2010).

---

23 The paper compares the business cycle stylised facts of seven Asian economies for the period 1960-1984 and 1984-1996. The mean volatility declines from 3.00 in the first sub-period to 2.00 in the second sub-period.
4.2 Structural Change or the Good Luck Hypothesis

Since the mid 1990s, the Indian economy has undergone a significant transformation in many aspects. A common dimension of this transition is the shift away from state domination towards a market economy. Were changes in the Indian business cycle from 1950 - 2010 driven by "good luck" - a reduction in the variance of exogenous shocks - or structural changes caused by liberalization policy, or better policies? If changes in the nature of the Indian business cycle were driven by structural changes, which features of India’s structural transformation are responsible for the stylized facts reported in Section 4?

1. The variance of exogenous shocks: The good luck hypothesis, the reduction in volatility caused by less frequent and/or smaller exogenous shocks, is typically attributed as a potential cause of a decline in volatility of aggregate economies. Two of the main candidates for exogenous shocks used in the literature are oil shocks and productivity shocks. The first plot of Figure 2 shows the cyclical component of TFP from 1980-2010. The standard deviation increases from .21 to .27 in the post reform period. The second graph plots the cyclical component of WPI (fuel). The standard deviation increases from 2.29 in 1982 - 1991, to 4.83 from 1992 - 2011. The first graph (second row) plots the cyclical component of the Brent crude oil price. The standard deviation marginally increases from 19.49 (1980-1990) to 19.73 (1992-2011). The evidence therefore doesn’t support the good luck hypothesis as the cause of the changing pattern of Indian business cycles in the post reform period.

2. Explaining volatility: While volatility has fallen in several business cycle indicators in the post reform period, aggregate volatility still remains high as in other emerging and developing economies who have experienced structural changes. One source of volatility is that while the transformation of the Indian economy to a more open economy in the post reform period has been accompanied by high growth, there has also been a sharp increase in India’s integration on both trade and financial flows. Figure 2 also shows the evolution of current and capital account flows expressed as a percent to GDP. In the pre-reform period

---

24Appendix C details how TFP has been calculated. Our TFP calculations are from 1980 onwards because of the lack of reliable data for years before.

25The data for WPI (fuel) is sourced from the website of the Office of the Economic Adviser to the Government of India, Ministry of Commerce and Industry available at [http://eaindustry.nic.in/](http://eaindustry.nic.in/)
the flows on current and capital account were around 20% of GDP. The conducive policy environment has resulted in both current and capital account flows to GDP ratio rising to around 60% each in 2009. These flows account for one source of high volatility.  

3. Consumption volatility: As shown in Table 2, consumption volatility has increased. [Aguiar and Gopinath (2007)] suggest that consumption volatility is high because of permanent productivity shocks, i.e., consumption volatility is driven by shocks to income that are larger or more persistent than they should be. This leads to a larger Solow residual, which is consistent with the increase in volatility documented of exogenous shocks documented in Figure 2. To the extent that increasing international financial integration allows countries to better smooth consumption through international risk sharing, an increase in consumption volatility is a puzzle. As noted before, our findings are consistent with the large literature on the apparent disconnect between the theoretical predictions of the financial liberalization process, and country specific findings.

4. Declining share of agriculture: Figure 3 shows a consistently declining share of agriculture since 1950s. Table 3 shows the changing compo-

---

26Another source of volatility is when productivity shocks get amplified by frictions as in [Aghion et al. (2004)]. Here, excess output volatility results because of capacity under-utilization. [Aghion et al. (2010)] show however that there is not much evidence that investment responds more to productivity shocks in economies with less good capital markets. On the other hand, [Aghion et al. (2010)] paper also finds that the fraction of long term investment in total investment is more pro-cyclical in economies with less good capital markets. If long run investment enhances productivity, then the reform story made explicit in this paper acquires salience.

27In the pre-reform period India was sheltered from external competition through high import duties and other barriers to trade. The capital account was also subject to strict regulations on inflows and outflows. Since the adoption of liberalisation policy, the restrictions on current and capital account have been eased. This has resulted in India being globally financially integrated. An effective way of measuring the openness is to sum the earnings and payments on the current and capital account and express the sum as a percent to GDP.
position of Indian GDP, the decline in the share of agriculture has been matched with a rise in the share of services. The fact that monsoon shocks matter less is evident from the declining share of agriculture in Indian GDP. It is well known that the service sector is typically more resilient than the agriculture and industrial sector in developing economies.

5. The investment-output ratio: From a purely monsoon driven economy, fluctuations in the economy are now driven primarily by fluctuations in inventory and investment. The share of investment in GDP has increased from 13% in 1950-51 to 35% in 2009-10. The increase has been particularly prominent since 2004-05. Figure 2 shows the time series of private corporate gross capital formation expressed as a percent to GDP. In recent years we can see the emergence of the behaviour found in the conventional business cycle. In the investment boom of the mid-1990s, private corporate GCF rose from 5% of GDP in 1990-91 to 11% of GDP in 1995-96. This then fell dramatically in the business cycle downturn to 5.39% in 2001-02, and has since recovered to 17.6% in 2007-08. The recent recession has led to its fall to 13.5% in 2009-10.

6. Better Policies Better policy is typically viewed as an improvement in the performance of fiscal and monetary policy. As noted in Section 4, government expenditures are less volatile in the post reform period, even though they are still more volatile than output. With respect to monetary policy, the definition of "better policies" typically refer to adherence to policy rules. However finds that the evidence supporting that monetary policy by the RBI can be captured by a Taylor Rule, with the interest rate as the policy instrument, is weak. Further, as discussed in Section 4, Table 2 shows a clear pro-cyclical monetary policy in the post-reform period. Indeed, a key feature that distinguishes emerging market economies from developed economies is the pro-cyclicality of monetary policy.

29 The fifth plot shows the behaviour of the consumption-output ratio from 1950-2010. The graphs show that while the share of private consumption has declined, there is a gradual and consistent increase in the share of investment in GDP.
Figure 2 The story of India’s transition
In sum the structural changes induced by liberalization policy appears to have been the primary factor behind the emergence of a conventional business cycle. In the pre-reform period, the Indian economy was characterised by controls on capacity creation and barriers to trade. In such a scenario, conventional business cycles characterised by an interplay of inventories and investment did not exist. One prominent source of investment was government investment in the form of plan expenditure, which did not show any cyclical fluctuations. In the present environment with eased controls on capacity creation and dismantling of trade barriers, private sector investment as a share of GDP has shown a significant rise.

5 Robustness Checks

In this section we perform a variety of robustness checks to test the validity of our results.

5.1 Robustness of Correlation Results

Following (Ambler et al., March, 2004), we investigate whether our correlation results are mere statistical noise or are robust to procedures for testing the statistically significant difference in correlation.

Table 4 shows the difference in correlation and the associated p-value. The application of the test shows that the difference in correlation between the pre and post-reform period is statistically significant for investment, imports,

The procedure for testing the statistically significant difference in correlation involves the following steps:

- Let $r_1$ be the correlation between the two variables for the first group with $n_1$ subjects.
- Let $r_2$ be the correlation for the second group with $n_2$ subjects.
- To test $H_0$ of equal correlations we convert $r_1$ and $r_2$ via Fisher’s variance stabilizing transformation
  \[ z = \frac{1}{2} \times \ln[(1 + r)/(1 - r)] \]
  and then calculate the difference:
  \[ z_f = (z_1 - z_2)/\sqrt{1/(n_1 - 3) + 1/(n_2 - 3)} \]
- The difference is approximately standard normal distribution.
- If the absolute value of the difference is greater than 1.96 (assuming 95% confidence interval) then we can reject the null of equal correlations.
net exports and the nominal exchange rate, as well as for both narrow and broad definitions of money, and CPI inflation. As mentioned before, these are the variables that drive the transition in the economy from the pre to post reform period.\textsuperscript{31}

\begin{table}[h]
\centering
\begin{tabular}{lll}
\hline
Variables (X\&Y) & Difference in correlation (z) & P-value \\
\hline
Private Consumption and output & -1.92 & 0.054 \\
Investment and output & -2.61 & 0.0089* \\
CPI and output & -0.77 & 0.44 \\
Exports and output & -0.88 & 0.37 \\
Imports and output & -3.49 & 0.0004* \\
Government expenditure and output & -1.15 & 0.25 \\
Nominal exchange rate and output & 2.08 & 0.037* \\
Net exports and output & 3.63 & 0.000278* \\
Narrow Money and output (M1) & -2.11 & 0.03* \\
 Broad Money and output (M3) & -2.61 & 0.0088* \\
Reserve Money and output & -2.65 & 0.0079* \\
CPI Inflation and output & -2.87 & 0.0004* \\
\hline
\end{tabular}
\caption{Difference in correlation and p-value}
\end{table}

For private consumption, CPI, exports and government expenditure, the test results are not significant. This implies that the nature of correlation of these variables with output does not change between the pre and post reform period.

5.2 Using Quarterly Data

In this section we present the results with quarterly data to check whether the results are consistent with results for the post-reform period in the annual data. The quarterly data for GDP is available from 1999 Q2, hence our quarterly data analysis starts from 1999 Q2. Figure 3 shows the detrended path of the key variables with output proxied by GDP. The cyclical component of the GDP series is placed in each panel of the figure to gauge the relative volatility and co-movement of each series in question with the reference series.

Business cycle stylised facts for key variables are provided in Table 5.\textsuperscript{31}

\textsuperscript{31}As an example, these results imply that the difference in the cyclical relation between, say, investment and output, is statistically significant between the pre and post reform period.
Volatility: Table 5 shows private consumption as more volatile than output. This is similar to the finding for other developing economies. In general, consumption is 40 percent more volatile than income in developing economies. Conversely, in developed economies the ratio is slightly less than one on average (Aguiar and Gopinath 2007). Table 5 reports the relative volatility of private consumption for India as 1.31.

Prices are also more volatile than output. Again, this is consistent with the findings for developing economies. In Latin American countries, prices are six times more volatile than output (Male 2010). The relative volatility of price level for India is 1.09.

Exports and Imports exhibit significant volatility. Higher export and import volatility can also be seen for developed economies, though the extent of volatility is lower (Kim et al. 2003). For India, the relative volatility of exports and imports are 7.40 and 7.52 respectively. Net exports are also found to be more volatile than output.

Consistent with the business cycle facts for developing economies, government expenditure is more volatile than output. The relative volatility of government expenditure is 5.53. Thus on volatility, our business cycle features resemble those of developing and emerging market economies.

Co-Movement: Table 5 shows investment as significantly pro-cyclical. The contemporaneous correlation of investment with output is 0.69. The strong correlation between investment and output for India provides evidence for a growing resemblance between India and advanced economies business cycles. This is consistent with the results from annual data.

Table 5 shows imports as pro-cyclical, while exports as mildly pro-cyclical. Again, this feature indicates resemblance between Indian and advanced economies business cycle facts.

For fiscal policy to play a stabilising role in an economy, government expenditure should be counter-cyclical. A significant difference between the annual and quarterly data analysis pertains to the correlation of government expenditure with output. For the annual analysis, the relation is counter-cyclical, though not significant. With the quarterly analysis, which pertains to recent data, we report a significant counter-cyclical relation between government expenditure and output. The correlation coefficient is -0.35. Crucially, this is similar to the findings for developed economies.

<td>0.66</td>
</tr>
</tbody>
</table>

Also consistent with the results of the annual post-reform period, nominal exchange rate is found to be counter-cyclical. Both narrow money (M1) and reserve money are found to be pro-cyclical.

Persistence Using quarterly data, Table 5 shows persistent output fluctuations for the Indian business cycle. The magnitude of persistence is comparable to those of developed economies. Male (2010) finds the average persistence for developed economies to be 0.84 and for developing economies to be 0.59. The persistence of output for India is higher than the developing economies average figure. The persistence is even higher at 0.84 if non-agricultural GDP is taken as the aggregate measure of business cycle activity.\(^{32}\) Price levels are also significantly persistent. Other variables in Table 5 are also found to be significantly persistent (with the exception of government expenditure and real interest rate).

In summary, the results of the quarterly data analysis broadly confirm the findings of the post-reform period using annual data. The findings support that the Indian economy is in a transition phase. While on volatility, the business cycle features resemble those of developing economies, the correlation and persistence results show growing similarity with the advanced economies business cycle.

\(^{32}\)These results are available from the authors on request.
5.3 The Baxter-King Filter with Annual Data

As another sensitivity measure, we check the robustness of our annual results to the choice of the de-trending technique. Following Stock and Watson (1999); Agenor et al. (2000) we use the Baxter-King to derive the business cycle properties of our macroeconomic variables. Baxter-King filter belongs to the category of band-pass filters that extract data corresponding to the chosen frequency components. We are interested in extracting the business cycle components. In line with the NBER definition, the business cycle periodicity is defined as those ranging between 8 to 32 quarters.

Table 6 reports the results with the cyclical components derived from the Baxter-King filter. The results are broadly consistent with those corresponding to the Hodrick-Prescott filter. Output volatility shows a decline in the post-reform period. On correlation, the results are broadly the same. Investment becomes pro-cyclical in the post-reform period. Exports is insignificantly pro-cyclical while the cyclicality of imports is significant. Since exports is acyclical and imports are pro-cyclical, net exports are found to be counter-cyclical. Similar to the findings with the Hodrick-Prescott filter, nominal exchange rate becomes counter-cyclical in the post-reform period, though the level of significance varies. Monetary policy is also found to be pro-cyclical in the post reform period.

There are some notable differences in the results related to volatility. This arises due to differences in the properties of the two filters. While the Baxter-King filter belongs to the category of band-pass filters that remove slow moving components and high frequency noise, the Hodrick-Prescott filter is an approximation to a high-pass filter that removes the trend but passes high frequency components in the cyclical part. The Baxter-King filter, however tends to underestimate the cyclical component. (Rand and Tarp, 2002)

As an example, in contrast to the findings of the Hodrick-Prescott filter, the absolute volatility of private consumption declines in the post-reform period, when the Baxter-King filter is used to de-trend the variables. The statistical testing procedure shows that the difference in correlations is close to the cut-off value of 1.96, even though it is not as strong as with the Hodrick-Prescott filter.

There are also notable differences with respect to persistence compared to the HP filter. Persistence in the pre-reform period for almost all the variables is low. Real GDP, consumption, and exports have negative persistence. In

\[33\text{For a detailed comparison of the filtering procedure of Hodrick-Prescott and Baxter-King, refer to } \text{Baxter and King (1999)}\]
the post reform period, persistence rises, but the variables are less persistent compared to when the HP filter is used to extract cycles.

5.4 Redefining the Sample Period

For the sake of completeness, we check the robustness of our results to a change in the sample period. To maintain uniformity in sample size we redefine the pre-reform period as starting from 1971.

Table 7 reports business cycle facts when the pre-reform period is defined as starting from 1971. The broad stylised facts remain the same. On correlation, our results remain the same as reported in Table 2. Investment and imports become highly pro-cyclical, while net exports and nominal exchange rate turn counter-cyclical in the post-reform period. On volatility, we get a mixed picture. While aggregate GDP is highly volatile at 2.24 in the pre-reform period, it falls to 1.78 in the post-reform period. Other variables, with the exception of investment, exports, imports and net exports also show a fall in volatility from the pre to post reform period.

6 Conclusion and Future Work

Documenting business cycle stylised facts forms the foundation of quantitative general equilibrium models either in the RBC or the New Keynesian DSGE tradition. Such a study assumes greater relevance in the context of an economy like India which has undergone significant transformation since 1991. The industrial sector has been freed from capacity controls, import duties have been reduced and a reasonably conducive environment towards the global economy has evolved over the last few years. The novel aspect of this paper is to present a comprehensive set of stylized facts governing
an economy in transition. We locate facts about Indian business cycles in
the context of other industrial economies, as well as other emerging and
developing countries.

The paper’s main contribution is to highlight the difference in the properties
of the Indian business cycle stylised facts over the two periods, and suggest
reasons for these changes. Our main finding is that after the liberalisation of
the Indian economy in 1991, in terms of volatility, key macroeconomic vari-
ables are less volatile in the post reform period compared to the pre-reform
period. However, consumption volatility has increased in the post reform pe-
riod, and the volatility of several macroeconomic variables in the post-reform
period in India is still high and similar to emerging market economies. In con-
trast, in terms of co-movement and persistence, India looks more similar to
advanced economies, and less like emerging market economies. The chang-
ing pattern of India’s business cycle suggests that there are links between
development stages and macro cycles, an area for future research.

Future work can use the findings of this paper to assess the extent to which
DSGE models, starting with the simplest RBC model through to New-
Keynesian models with labour markets and financial frictions introduced in
stages, can explain business cycle fluctuations in India. Both closed and
open economy models can be examined. Comparisons with a representative
developed economy, say the US, can then be made. Proceeding in this way,
one will be able to assess the relative importance of various frictions in driv-
ing aggregate fluctuations in India. Another avenue for future work relates
to [Lucas 1987], which pointed out that the welfare gains from eliminating
business cycle fluctuations in the standard RBC model are small, and dwarfed
by the gains from increased growth. While adding New Keynesian frictions
significantly increases the gains from stabilization policy, they still remain
small compared to the welfare gains from increased growth. However, there
is relatively little work introducing long-run growth into DSGE models, and
exploring the relationship between volatility and endogenous growth. This
takes particular importance for India which has moved to a higher growth
path in recent years, with the attendant decline in macroeconomic volatility,
as documented in this paper.

B Statistical Methodology

In choosing the technique to derive the cyclical component, the literature on stylised facts mainly relies on either the Hodrick-Prescott filter \cite{King:1999} or the band-pass filter proposed by Baxter and King \cite{Stock:1999}. We use the Hodrick-Prescott filter \cite{Hodrick:1997} to de-trend the series and then check the robustness of our results with the Baxter-King filter \cite{Baxter:1999}.

For annual data analysis, the log transformed series is passed through a filter to extract the cyclical (stationary) and trend (non-stationary) component. In case of quarterly data, the variables are adjusted for seasonal fluctuations using the \textit{x-12-arima} seasonal adjustment program. Once adjusted for seasonality, the series are transformed to log terms and then filtered to extract the cyclical and trend component.

The Hodrick-Prescott method involves defining a cyclical output $y_c^t$ as current output $y_t$ less a measure of trend output $y_t^g$ with trend output being a weighted average of past, current and future observations:

$$y_c^t = y_t - y_t^g = y_t - \sum_{j=-J}^{J} a_j y_{t-j}$$

After de-trending the series to obtain the cyclical components, we can then determine the properties of the business cycle. In the subsequent analysis, all references to the variables refer to their cyclical component. The cyclical component of the variable is used to derive the volatility, co-movements and persistence of variables.

Our definition of these terms is standard in the literature. Volatility is a measure of aggregate fluctuations in the variable of interest. It is measured by the standard deviation of the variable. Relative volatility is the ratio of volatility of the variable of interest and the variable used as a measure of aggregate business cycle activity. A relative volatility of more than one implies that the variable has greater cyclical amplitude than the aggregate business cycle.

Contemporaneous co-movements with output series indicate the cyclicality of key macroeconomic variables. In particular, the degree of co-movement of a variable

---

\[34 \] A large literature exists on the choice of the de-trending procedure to extract the business cycle component of the relevant time series \cite{Canova:1998,Burnside:1998,Bjornland:2000}. Canova \cite{Canova:1998} argues that the application of different de-trending procedures extract different types of information from the data. This results in business cycle properties differing widely across de-trending methods. However, commenting on Canova \cite{Canova:1998}, Burnside \cite{Burnside:1998} shows through spectral analysis, that the business cycle properties of variables are robust to the choice of the filtering methods if the definition of business cycle fluctuations are uniform across all the de-trending methods.
of interest $y_t$ with the measure of aggregate business cycle $x_t$ is measured by the magnitude of correlation coefficient $\rho(j)$ where $j$ refers to leads and lags (Agenor et al., 2000). The variable is considered to be pro-cyclical if the contemporaneous coefficient $\rho(0)$ is positive, a-cyclical if the contemporaneous coefficient $\rho(0)$ is zero and counter-cyclical if the contemporaneous coefficient $\rho(0)$ is negative.

Finally, persistence indicates the inertia in business cycles. It also captures the length of observed fluctuations. This is measured by the first order auto-correlation coefficient. A high coefficient implies a persistent, long economic fluctuation. Positive coefficients indicate that high values follow high values, or low values follow low values. Negative coefficients indicate reversals from high to lower values, or vice-versa.

### C Estimation of Aggregate TFP for India

The methodology for calculating TFP is as follows. The series for sectoral GDP and net capital stock is rebased at 2004-05 prices to arrive at a longer time series. We use the distribution of labour force (per 1000 households, male/female, rural/urban) as reported for each sector in the NSSO’s quinquennial Employment Unemployment Survey as well as in the annual surveys based on a thin sample to generate a time series of the distribution of sectoral employment. Using the sectoral distribution of labour force and the total labour force data published by the World Bank, we obtain sectoral employment series. We then compute the sectoral TFP series for India using sectoral real GDP, net fixed capital stock and employment data. Given the availability of employment data, our measure of TFP series spans 1980-2009.

Using the sectoral shares ($w^j_s$) of capital, labour and land in agriculture, industry and services from Verma (2008), we then measure the sectoral TFP series as

$$
\log(A^s_t) = \log(Y^s_t) - \sum_{j=1}^{n_s} w^j_s \log(X^j_t), \quad \sum_{j=1}^{n_s} w^j_s = 1,
$$

where $n_s$ is the number of inputs used in sector $s$. Here $s$ denotes major sectors constituting the economy namely, agriculture, industry and services, $Y$ represents real GDP and $X^j$ denotes factors of production in the respective sector. For example when, $s =$ agriculture, $j =$ land, physical capital, labour. When $s =$ industry, services, $j =$ physical capital, labour.

Finally, aggregate TFP is measured as a weighted average of the sectoral TFPs as following:

$$
\log(A_t) = \sum_s \log(A^s_t), \quad s = \text{Agriculture, Industry, Services}
$$

About ICRIER

Established in August 1981, ICRIER is an autonomous, policy-oriented, not-for-profit economic policy think tank. ICRIER's main focus is to enhance the knowledge content of policy making by undertaking analytical research that is targeted at improving India's interface with the global economy. ICRIER's office is located in the prime institutional complex of India Habitat Centre, New Delhi.

ICRIER’s Board of Governors comprising leading policy makers, academicians, and eminent representatives from financial and corporate sectors is presently chaired by Dr. Isher Ahluwalia. ICRIER’s team is led by Dr. Parthasarathi Shome, Director and Chief Executive.

ICRIER conducts thematic research in the following seven thrust areas:

- Macro-economic Management in an Open Economy
- Trade, Openness, Restructuring and Competitiveness
- Financial Sector Liberalisation and Regulation
- WTO-related Issues
- Regional Economic Co-operation with Focus on South Asia
- Strategic Aspects of India’s International Economic Relations
- Environment and Climate Change

To effectively disseminate research findings, ICRIER organises workshops, seminars and conferences to bring together policy makers, academicians, industry representatives and media persons to create a more informed understanding on issues of major policy interest. ICRIER invites distinguished scholars and policy makers from around the world to deliver public lectures on economic themes of interest to contemporary India.
